Abstract. The graph neural network has developed by leaps and bounds in recent years. This review summarizes the main spectral-based graph neural networks and related fundamentals of spectral graph theory. In addition, the technical details of the graph neural networks defined on the spectral domain will be discussed.

Keywords: spectral graph theory, graph neural network

1 Introduction

Convolutional Neural Networks (CNNs) are effective techniques for addressing numerous machine learning and data mining problems, achieving promising performance in image processing, speech recognition, computer vision, and game of go [26], [28], [21], [24], [39], in which there is an underlying Euclidean structure [1]. Such grid-like data is easy to be exploited by convolutional architectures [27]. However, the nature of data defined on non-Euclidean domains [2] implies that there are no such familiar properties as global parameterization, a common system of coordinates, vector space structure, or shift-invariance [22] (further details or other solution can be seen in [44], [42]), e.g., the characteristics of users in social networks can be modeled as signals on the vertices of the social graph [25]; papers linked to each other via citations can be categorized into different groups according to topics [41]; traffic data of different roads and times can be modeled as graph structure signals [9]. Generally, graphs are ubiquitous in the real world, standing for objects and their relationships such as social networks, e-commerce networks, biology networks, and traffic networks [45].

Graph deep learning is an umbrella term for emerging techniques attempting to generalize (structured) deep neural models to non-Euclidean domains such as graphs and manifolds [2]. The notation of graph neural networks was first mentioned in M. Gori et al.(2005) [16], [43], and further developed and completed in Scarselli et al.(2009) [36], [43]. These early work presented graph neural networks which need high computationally expensive training that learn the target

[1] Euclidean data is which we could compute standard inner products, subtract one vector from another, apply matrices to vectors, etc. For example, data like time signal and images were further discretized on regular Cartesian grids, also could be applied operations like convolution by simply sliding the same window over the signal and computing inner products.

node's representation by propagating neighbor vertex or link information via the recurrent neural network in an iterative way until a stable convergence is achieved [10], [31], [43].

Graphs are generic data representation forms that are useful for illustrating the geometric structures of data domains in a great number of applications, including social, energy, transportation, sensor, and neural networks [38]. With the advance of computational hardware and research output, deep learning has big progress and achieves great success in many fields including translation, object recognition, recommendation systems, etc, which greatly boost human beings' convenience and enrich people's life experience. Currently, most deep learning methods such as LSTM and CNN are good at processing sequence data, image data, video data, text data, and others defined on Euclidean domain. However, most deep learning algorithms perform not very well at data on non-Euclidean domains. By contrast, graph neural network, which is the current popular topic in the deep learning area, can achieve a good performance on non-Euclidean domains. Graph neural networks can be provided a taxonomy that divides graph neural networks into five categories, graph convolutional networks, graph attention networks, graph autoencoders, and graph generative networks [43]. Here, we mainly introduce graph convolutional neural networks on the spectral domain, and also the basics of spectral graph theory. About the recent years of graph convolutional neural networks (GCNs) can be listed as the following; The first spectral graph neural networks can be traced to GCN which is based upon a hierarchical clustering of the domain, and another based on the spectrum of the graph Laplacian respectively [3]. Chebyshev GCN (ChebNet) utilizes Chebyshev polynomials to fit convolution kernels to reduce computational complexity [11]. Another related work [40] proposes an accelerated algorithm based on the Lanczos method that adapts to the Laplacian spectrum without explicitly computing it, and achieves higher accuracy without increasing the overall complexity significantly compared to methods based on Chebyshev polynomials. GCN, a scalable approach for semi-supervised learning on graph-structured data that is based on an efficient variant of convolutional neural networks, can operate directly on graphs [23]. Graph Convolutional Recurrent Network (GCRN), a generalization of classical recurrent neural networks (RNN) and graph CNN, can predict structured sequences of data, which represent series of frames in videos, spatio-temporal measurements on a network of sensors, or random walks on a vocabulary graph for natural language modeling [37]. CayleyNets GCN introduces a new spectral-domain convolutional architecture for deep learning on graphs based on Cayley filters instead of Chebyshev filters [30]. Graph attention networks (GATs), a novel neural network architectures defined on spatial domain, by specifying different weights to different nodes in a neighborhood without requiring any kind of costly matrix operation (such as inversion) or depending on knowing the graph structure upfront, that operate on graph-structured data, leveraging masked self-attentional layers to solve the shortcomings of prior methods based on graph convolutions or their approximations [41]. The disadvantage of spectral based GCN is that the learned filters depend on the Laplacian eigen-

basis, depending on the graph structure, which in turn means a model trained on a specific structure that can not be directly extended to a graph with a different structure [41].

The first motivation of graph neural network stems from CNNs which have been successfully applied in the field of computer vision [29], [28], [46], [12]. CNNs are essentially a high-performance end to end learning framework [2] for processing image information, but it can only operate on regular Euclidean data like 2D grid and 1D sequence [46]. Besides, the characteristics of CNNs: local connection, shared weights and the use of multi-layer is of great importance in addressing problems in graph domain [26], [46], since 1) graphs are the most typical locally connected structure. 2) shared weights reduce the computational cost compared with traditional spectral graph theory [6], [46]. To introduce the graph neural network, we need first to associate it with graph spectral theory, whose focus is to examine the eigenvalues (or spectrum) of a matrix associated with a graph and utilize them to determine structural properties of the graph [6].

The graph itself can be heterogeneous or homogenous [45], and the targets of GCN can focus on different graph analytics tasks with one of the following mechanisms [43], [45].

- *Node-level*: tasks about predicting the node for regression or classification.
- *Edge-level*: tasks about predicting the edge or link for classification.
- *Graph-level*: tasks about predicting graph for classification.

GCNs approaches are classified into two categories, spectral-based and spatial-based methods [43]. Here, we introduce the basics of spectral graph theory according to [8], and restate the methods of graph convolutional neural networks (GCNs), with a focus on spectral graph neural network.

2 Basic graph concepts

A graph can be defined as $\mathcal{G} = (\mathcal{V}, \mathcal{E}, A)$, where $\mathcal{V}$ is the set of vertices or nodes, $\mathcal{E}$ is set of edges or links, and A is the adjacency matrix of size $n \times n$. $v_i \in \mathcal{V}$ denotes a node, and $e_{i,j} \in \mathcal{E}$ denotes an edge connecting v_i and v_j in a graph $\mathcal{G}$. If an edge $e_{i,j}$ exists in graph, denoted by $e_{i,j} \in \mathcal{E}$, then $A_{i,j} > 0$, otherwise $A_{i,j} = 0$ and $e_{i,j} \notin \mathcal{E}$.

Degree of vertex: The degree of node i is d_i, representing the number of edges connected to node i,which is defined by

$$d_i = \sum_{j=1}^{n} \mathbb{1}_{\mathcal{E}}\{e_{i,j}\} \tag{1}$$

where $\mathbb{1}$ is indicator function.

[2] End-to-end learning refers to training a possibly complex learning system by applying gradient-based learning to the system as a whole [14].

Given a graph $\mathcal{G}$, the degrees matrix $D \in \mathbb{R}^{n\times n}$ is

$$D_{i,j} = \begin{cases} d_i & \text{if } i = j \\ 0 & \text{otherwise} \end{cases} \tag{2}$$

Undirected graph is graph with undirected edges and has $A_{i,j} = A_{j,i}$. In contrast, directed Graph is graph with directed edges, which may not satisfy $A_{i,j} \neq A_{j,i}$. The spectral graph convolutional network is defined on an undirected graph. In fact, an undirected graph is a special case of a directed graph.

Diameter of graph [1]: Given a connected graph $\mathcal{G}$, for two vertices v_a and $v_b \in \mathcal{V}$, a path between v_a and v_b is a sequence $\pi = (e_1, e_2, ..., e_k)$ where $e_i = (v_{i-1}, v_i) \in \mathcal{E}$ and $v_i \in \mathcal{V}$ for $i \in 1, ..., k$ with $v_0 = v_a$ and $v_k = v_b$. We denote $e \in \pi$ if the edge $e \in \mathcal{E}$ belongs to the path π, i.e., if $e = e_i$ for an $i \in 1, ..., k$. The distance between two vertices v_i and v_j is the number of edges in $\mathcal{E}$ in the shortest path connecting these two vertices, denoted by

$$dist(v_i, v_j) = \min \sum_{e\in\pi} w_e \tag{3}$$

where w_e is the weight on the edge e, $w_e = 1$ if it applies to unweighted graph.

The diameter of $\mathcal{G}$, denoted by $diam(\mathcal{G})$, is the maximum graph distance between any pair of vertices in $\mathcal{V}$, i.e.

$$diam(\mathcal{G}) = \max\{dist(v_i, v_j), v_i, v_j \in \mathcal{V}\} \tag{4}$$

This concept is useful to explain why spectral filters of ChebNet are exactly K-localized.

3 Laplacian matrix

Weight on the graph is an associated numerical value assigned to each edge of a graph. A weighted graph is a graph associated with a weight to each of its edges, instead, an unweighted graph is one in which each edge does not have any weight associated with it. The Laplacian matrix (unnormalized Laplacian or combinatorial Laplacian) for an unweighted graph is

$$L = D - A \in \mathbb{R}^{n\times n} \tag{5}$$

Analogously, weighted graph is

$$L = D - W \in \mathbb{R}^{n\times n} \tag{6}$$

where W is weighted adjacent matrix.

In graph theory, a regular graph is a graph in which each vertex has the same number of neighbors, i.e. each node has the same degree. k-regular graph is a regular graph with vertices of degree k.

When $\mathcal{G}$ is k-regular, it is easy to see that

$$\mathcal{L} = I - \frac{1}{k}A = \frac{1}{k}L \tag{7}$$

or

$$\mathcal{L} = I - \frac{1}{k}W = \frac{1}{k}L \tag{8}$$

• Random-walk normalization:

$$\mathcal{L} = I - D^{-1}A \tag{9}$$

In addition, the other Laplacian matrix, namely signless Laplacian, denoted by L_s, is defined as $L_s = D + A$.

Eigen decomposition, also known as spectral decomposition, is a method to decompose a matrix into a product of matrices involving its eigenvalues and eigenvectors. Assuming basis of $\mathcal{L}$ is $U = (\overline{u}_1, \overline{u}_2, ..., \overline{u}_n)$, $\overline{u}_i \in \mathbb{R}, i = 1, 2, ..., n$. Considering the Laplacian matrix is real symmetric matrix, the spectral decomposition of Laplacian matrix is

$$\mathcal{L} = U\Lambda U^{-1} = U\Lambda U^T \tag{10}$$

$$\Lambda = \begin{bmatrix} \lambda_1 & & & \\ & \lambda_2 & & \\ & & \ddots & \\ & & & \lambda_n \end{bmatrix} = diag([\lambda_1, ..., \lambda_n]) \in \mathbb{R}^{n \times n} \tag{11}$$

Usually, the Laplacian matrix we referred is normalized Laplacian [5, Section 1.3]. It is easy to see that the Laplacian matrix L associated with an undirected graph is positive semi-definite: Let $f = \{f_1, f_2, ..., f_n\}$ be an arbitrary vector, then

$$\begin{gathered} f^T L f = f^T D f - f^T W f = \sum_{i=1}^{n} D_{i,i} f_i^2 - \sum_{i,j}^{n} f_i f_j W_{i,j} \\ = \frac{1}{2}(\sum_{i=1}^{n} D_{i,i} f_i^2 - 2\sum_{i=1}^{n}\sum_{j=1}^{n} f_i f_j W_{i,j} + \sum_{j=1}^{n} D_{j,j} f_j^2) \\ = \frac{1}{2}(\sum_{i=1}^{n}\sum_{j=1}^{n} W_{i,j}(f_i - f_j)^2) \geq 0 \end{gathered}$$

these are basic facts that simply follow from L's symmetric and positive semi-definite properties:

• L of order n have n linearly independent eigenvectors.

• The eigenvectors corresponding to different eigenvalues of L are orthogonal to each other, and the matrix formed by these orthogonal eigenvectors normalized to the unit norm is an orthogonal matrix.

• The eigenvectors of L can be taken as real vectors.

• The eigenvalues of L are nonnegative.

Normalization of Laplacian matrix $\mathcal{L}$ include:

• Symmetric normalization:

$$\mathcal{L} = D^{-1/2} L D^{-1/2} = I - D^{-1/2} W D^{-1/2} \tag{12}$$

with the convention $D_{i,i}^{-1} = 0$ for $d_i = 0$, particularly, node i is an isolated vertex if $d_i = 0$. A graph is said to be non-trivial if it contains at least one edge [8, Section 1.2]. The normalized Laplacian has eigenvalues always lying in the range between 0 and 2 inclusive as demonstrated by Chung [8, Section 1.3].

Laplacian operator: The Laplacian matrix essentially is a Laplacian operator on a graph. To illustrate this concept, we introduce the incidence matrix. The incidence matrix is a matrix that reflect the relationship between vertices and edges. Suppose **the direction of each edge in the graph is fixed (but the direction can be set arbitrarily)**, let $f = (f_1, f_2, f_3, ..., f_n)^T$ denote signal vector associated with the vertices $(v_1, v_2, v_3, ..., v_n)$, the incidence matrix of a graph, denoted by ∇, is a $|\mathcal{E}| \times |\mathcal{V}|$ matrix, the incidence matrix is defined as follows:

$$\nabla_{i,j} = \begin{cases} \nabla_{i,j} = -1 & \text{if } v_j \text{ is the initial vertex of edge } e_i \\ \nabla_{i,j} = 1 & \text{if } v_j \text{ is the terminal vertex of edge of } e_i \\ \nabla_{i,j} = 0 & \text{if } v_j \text{ is not in } e_i \end{cases} \tag{13}$$

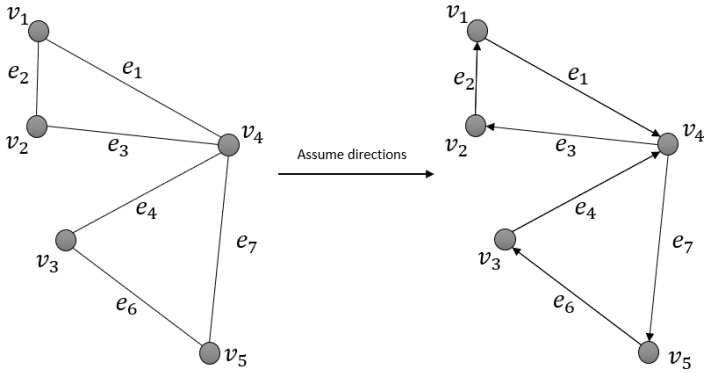

Fig. 1. Graph

The mapping $f \longrightarrow \nabla f$ is known as the co-boundary mapping of the graph, we take an example from the graph as shown in Fig. 1, we arrange arbitrary directions to the edges as the figure in right shows. We have $\nabla = \begin{bmatrix} -1 & 0 & 0 & 1 & 0 \\ 1 & -1 & 0 & 0 & 0 \\ 0 & 1 & 0 & -1 & 0 \\ 0 & 0 & -1 & 1 & 0 \\ 0 & 0 & 0 & -1 & 1 \\ 0 & 0 & 1 & 0 & -1 \end{bmatrix}$.

Then, we have $\nabla \begin{bmatrix} f_1 \\ f_2 \\ f_3 \\ f_4 \\ f_5 \end{bmatrix} = \begin{bmatrix} -1 & 0 & 0 & 1 & 0 \\ 1 & -1 & 0 & 0 & 0 \\ 0 & 1 & 0 & -1 & 0 \\ 0 & 0 & -1 & 1 & 0 \\ 0 & 0 & 0 & -1 & 1 \\ 0 & 0 & 1 & 0 & -1 \end{bmatrix} \begin{bmatrix} f_1 \\ f_2 \\ f_3 \\ f_4 \\ f_5 \end{bmatrix} = \begin{bmatrix} f_4 - f_1 \\ f_1 - f_2 \\ f_2 - f_4 \\ f_4 - f_3 \\ f_5 - f_4 \\ f_3 - f_5 \end{bmatrix}$

Correspondingly,

$$(\nabla f)(e_{i,j}) = f_j - f_i \tag{14}$$

where $e_{i,j}$ denote the edge connecting node i and node j.

Furthermore,

$$\nabla^T(\nabla f) = \begin{bmatrix} -1 & 1 & 0 & 0 & 0 & 0 \\ 0 & -1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 & 0 & 1 \\ 1 & 0 & -1 & 1 & -1 & 0 \\ 0 & 0 & 0 & 0 & 1 & -1 \end{bmatrix} \begin{bmatrix} f_4 - f_1 \\ f_1 - f_2 \\ f_2 - f_4 \\ f_4 - f_3 \\ f_5 - f_4 \\ f_3 - f_5 \end{bmatrix} = \begin{bmatrix} 2f_1 - f_2 - f_4 \\ 2f_2 - f_1 - f_4 \\ 2f_3 - f_4 - f_5 \\ 4f_4 - f_1 - f_2 - f_3 - f_5 \\ 2f_5 - f_3 - f_4 \end{bmatrix}$$

Accordingly,

$$Lf = (D-A)f = \begin{bmatrix} 2 & -1 & 0 & -1 & 0 \\ -1 & 2 & 0 & -1 & 0 \\ 0 & 0 & 2 & -1 & -1 \\ -1 & -1 & -1 & 4 & -1 \\ 0 & 0 & -1 & -1 & 2 \end{bmatrix} f = \begin{bmatrix} 2f_1 - f_2 - f_4 \\ 2f_2 - f_1 - f_4 \\ 2f_3 - f_4 - f_5 \\ 4f_4 - f_1 - f_2 - f_3 - f_5 \\ 2f_5 - f_3 - f_4 \end{bmatrix} = \nabla^T(\nabla f)$$

In fact, for any undirected graph,

$$Lf = \nabla^T(\nabla f) \tag{15}$$

Particularly, for an n-dimensional Euclidean space, the Laplacian operator can be considered as a second-order differential operator

Analogously, consider undirected weighted graphs $\mathcal{G}$, each edge $e_{i,j}$ is weighted by $w_{i,j} > 0$, the Laplace operator on the graph can be defined as

$$(Lf)_i = \sum_{j=1}^{n} W_{i,j}(f_i - f_j) \tag{16}$$

where $W_{i,j} = 0$ if $e_{i,j} \in \mathcal{E}$.

Also,

$$(Lf)_i = \sum_{j}^{n} W_{i,j}(f_i - f_j) = D_{ii}f_i - \sum_{j}^{n} W_{i,j}f_j = (Df - Wf)_i = (Lf)_i \tag{17}$$

For any i holds, then it can be general form:

$$(D - W)f = Lf \tag{18}$$

As a quadratic form,

$$f^T Lf = \frac{1}{2} \sum_{e_{i,j}} W_{i,j}(f_i - f_j)^2 \tag{19}$$

Therefore, graph Laplacian matrix L, intrinsically as a Laplacian operator, make the centre node subtracts the surrounding nodes in turn, multiplying the corresponding link weights at the same time, and then sums them.

The spectral GCN analysis relies on spectral graph theory, which studies the properties of graphs via the eigenvalues and its corresponding eigenvectors associated with the graph adjacency matrix and the graph Laplacian matrix and its variants. Since graph convolutional operator is defined on eigenvalues of the Laplacian matrix, being familiar with the properties of graph-related properties (as the facts listed below) is greatly helpful for the research on spectral GCN.

The eigenvalues of the Laplacian matrix can be inferred from the properties of the graph, for example:

Lemma 1 ([8, Section 1.3]). *The number of zero eigenvalues of the Laplacian (i.e. the multiplicity of 0 as an eigenvalue) is the number of connected components* [3] *of $\mathcal{G}$. In particular $\mathcal{G}$ is connected if and only if $\lambda_2 > 0$ (λ_2 is the second smallest eigenvalue, some references use λ_1). The multiplicity of 2 as an eigenvalue is the number of bipartite connected components of $\mathcal{G}$ with at least two vertices.*

Theorem 1. *The matrix $\mathcal{L}$ is positive semi-definite and satisfies: All eigenvalues lie in the interval $[0, 2]$.*

4 Discrete Signal Processing on Graphs

Graph filters, generally in discrete signal processing(DSP), is a system $H(\cdot)$ that takes a graph signal f as an input, processes it, and produces another graph signal $\tilde{f} = H(f)$ as an output [35], [34]. In discrete signal processing on graphs (DSPG) [34], an equivalent concept of filters for the processing of graph signals. Given graph signals f indexed by a graph , the fundamental building block for graph filters on G is a graph shift that replaces each signal coefficient f_i indexed by node n with a linear combination of coefficients at other nodes weighted proportionally to the degree of their relation [34]:

$$\tilde{f_i} = \sum_{m=1}^{n} W_{i,m} f_m \Leftrightarrow \tilde{f} = Wf \tag{20}$$

where W is the graph shift or a weighted adjacency matrix.

According to [33, Theorem 1], any linear, shift-invariant graph filter is necessarily a matrix polynomial in the (weighted) adjacency matrix W of the form

$$h(W) = h_0 I + h_1 W + ... + h_L W^L \tag{21}$$

The output of the filter (21) is the signal

$$\tilde{f} = H(f) = h(W)f \tag{22}$$

[3] A connected component or simply component of an undirected graph is a subgraph in which each pair of nodes is connected with each other via a path.

where $h_l \in \mathbb{C}$ are possible coefficients. In addition, $L \leq n$, which means any graph filter 21 can be represented by at most n coefficients. Also, if graph filter 21 is invertible, matrix $h(A)$ is non-singular, its inverse also is a matrix polynomial in W of the form 21, namely $g(W) = h(W)^{-1}$.

Generally, a Fourier transform is a uniform to the expansion of a signal using basis elements that are invariant to filtering. And the basis can be the eigenbasis of the W as 10 or the Jordan eigenbasis of W if the complete eigenbasis does not exist.

Graph Fourier transform is analogous to classical Fourier transform, similarly, the eigenvalues could represent graph frequencies and form the spectrum of the graph, eigenvectors denote frequency components which serve the work as the graph Fourier basis [34], [7].

Let graph Fourier basis $U = (u_1, u_2, ..., u_n)$, $u_i \in \mathbb{R}, i = 1, 2, ..., n$ from Laplacian matrix $\mathcal{L}$ as 10. Nodes' signal $f = (f_1, f_2, f_3, ..., f_n)^T$, after graph Fourier Transform, signal become $\hat{f} = (\hat{f}(\lambda_1), \hat{f}(\lambda_2), \hat{f}(\lambda_3), ..., \hat{f}(\lambda_n))^T$, the graph inverse Fourier transform is

$$\hat{f} = U^T f \tag{23}$$

Correspondingly, Graph Fourier transform is

$$f = U\hat{f} \tag{24}$$

Therefore, taking Laplace's eigenvector as the basis function, any signal on the graph can be

$$f = \hat{f}(\lambda_1)u_1 + \hat{f}(\lambda_2)u_2 + ... + \hat{f}(\lambda_n)u_n = \sum_{i=1}^{n} \hat{f}(\lambda_i)u_i \tag{25}$$

u_i is the column vector of orthogonal matrix from spectral decomposition from $L = U\Lambda U^T$.

In fact, that is analogous to the principle of Discrete Fourier Transform(DFT)

$$X_{2\pi}(k) = \sum_{n=-\infty}^{\infty} x_n e^{-ikn} \tag{26}$$

5 Spectral graph convolution

In the Fourier domain, the convolution operator on graph $\cdot_G$ is defined as

$$g(\cdot_G)f = \mathcal{F}^{-1}(\mathcal{F}(g) \odot \mathcal{F}(f)) = U(U^T g \odot U^T f) = U g_\theta(\Lambda)U^T f = g_\theta(\mathcal{L})f \tag{27}$$

where $(\cdot_G)$ is convolution operator defined on graph, $\odot$ is Hadamard product. It follows that a signal f is filtered by $g \in \mathbb{R}^n$, and denotes $g_\theta(\Lambda) = diag(U^T g)$ which the diagonal corresponds to spectral filter coefficients.

For details,

$$g_\theta(\cdot_G)f = g_\theta(\mathcal{L})f = g_\theta(U\Lambda U^T)f = Ug_\theta(\Lambda)U^Tf =$$
$$U\begin{bmatrix}\hat{g}(\lambda_1) & & & \\ & \hat{g}(\lambda_2) & & \\ & & \ddots & \\ & & & \hat{g}(\lambda_n)\end{bmatrix}U^Tf = U\begin{bmatrix}\hat{g}(\lambda_1) & & & \\ & \hat{g}(\lambda_2) & & \\ & & \ddots & \\ & & & \hat{g}(\lambda_n)\end{bmatrix}\hat{f} =$$
$$U\begin{bmatrix}\hat{g}(\lambda_1) & & & \\ & \hat{g}(\lambda_2) & & \\ & & \ddots & \\ & & & \hat{g}(\lambda_n)\end{bmatrix}\begin{bmatrix}\hat{f}(\lambda_1) \\ \hat{f}(\lambda_2) \\ \dots \\ \hat{f}(\lambda_n)\end{bmatrix} = U\begin{bmatrix}\hat{g}(\lambda_1) \\ \hat{g}(\lambda_2) \\ \dots \\ \hat{g}(\lambda_n)\end{bmatrix} \odot \begin{bmatrix}\hat{f}(\lambda_1) \\ \hat{f}(\lambda_2) \\ \dots \\ \hat{f}(\lambda_n)\end{bmatrix}$$

Spectral-based GCN all follow this definition of $Ug_\theta(\Lambda)U^Tf$, the main difference between different version of Spectral-based GCN lies in the choice of the filter $g_\theta(\Lambda)$ [43].

6 Different kinds of SGCN

6.1 Spectral CNN

Bruna et al. propose the first spectral convolutional neural network [4]. A graph can be associated with node signal $f \in \mathbb{R}^{n\times C_k}$ is a feature matrix with $f_i \in \mathbb{R}^{C_k}$ representing the feature vector of node i. A construction where each layer $k = 1, \dots, K$ transforms an input vector $f^{(k)}$ of size $n \times C_k$ into an output $f^{(k+1)}$ of size $n \times C_{k+1}$.

$$f_j^{(k+1)} = \sigma(U\sum_{i=1}^{C_k} g_{\theta_{i,j}^{(k)}}U^T f_i^{(k)}) = \sigma(U\sum_{i=1}^{C_k} g_{\theta_{i,j}^{(k)}}\hat{f}_i^{(k)}) \tag{28}$$

$$g_{\theta_{i,j}^{(k)}} = \begin{bmatrix}\theta_1^{(k)} & & & \\ & \theta_2^{(k)} & & \\ & & \ddots & \\ & & & \theta_n^{(k)}\end{bmatrix} \tag{29}$$

where $g_{\theta_{i,j}^{(k)}}, i = 1, ..., n; j = 1, ..., C_k$ is a diagonal matrix with trainable parameters $\theta_m^{(k)}, m \in (1, n)$, σ is activation function.

6.2 ChebNet

ChebNet [11] uses Chebyshev polynomials instead of convolutions in spectral domain. Furthermore, it was demonstrated that that $g_\theta(\Lambda)$ can be approximated by a truncated expansion in terms of Chebyshev polynomials [20].

$$T_{n+1}(x) = 2xT_n(x) - T_{n-1}(x), n \in \mathbb{N}^+ \tag{30}$$

where $T_0(x) = 1, T_1 = x$. Here, we make $\widetilde{\Lambda} = \frac{2\Lambda}{\lambda_{max}} - I_n \in [-1, 1]$, λ_{max} is the biggest eigenvalue from $\mathcal{L}$

$$g_\theta(\Lambda) = \sum_{k=0}^{K-1} \theta_k T_k(\widetilde{\Lambda}) \tag{31}$$

where the parameter $\theta \in \mathbb{R}^K$, $T_k(\widetilde{\Lambda}) \in \mathbb{R}^{n \times n}$. The filtering operator can also be written as

$$g_\theta(\mathcal{L})f = \sum_{k=0}^{K-1} \theta_k T_k(\tilde{\mathcal{L}})f \tag{32}$$

where $T_k(\tilde{\mathcal{L}}) \in \mathbb{R}^{n \times n}$ is the Chebyshev polinomial of order k evaluated at the scaled Laplacian $\tilde{\mathcal{L}} = 2\mathcal{L}/\lambda_{max} - I_n$. Accordingly, spectral filters represented by K^{th}-order polynomials of the Laplacian are exactly K-localized, i.e. it depends only on nodes that are at maximum K steps away from the central node [11], [20, Lemma 5.2].

Lemma 2 ([20, Lemma 5.2]). *Let $\mathcal{G}$ be a weighted graph, with adjacency matrix A. Let B equal the adjacency matrix of the binarized graph, i.e. $B_{m,n} = 0$ if $A_{m,n} = 0$, and $B_{m,n} = 1$ if $A_{m,n} > 0$. Let $\tilde{B}$ be the adjacency matrix with unit loops added on every vertex, e.g. $\tilde{B}_{m,n} = B_{m,n}$ for $m \neq n$ and $\tilde{B}_{m,n} = 1$ for $m = n$.*

Then for each $s > 0$, $(B^s)_{m,n}$ equals the number of paths of length s connecting m and n, and $(\tilde{B}^s)_{m,n}$ equals the numebr of all paths of length $r \leq s$ connecting m and n.

The Lemma can be used to demonstrate that matrix elements of low powers of the graph Laplacian corresponding to sufficiently separated vertices must be zero. Therefore, $dist(v_i, v_j) > K$ implies $(\mathcal{L}^K)_{i,j} = 0$, and the spectral filters of ChebNet are exactly K-localized.

Accordingly,

$$g_\theta(\Lambda) = \begin{bmatrix} \hat{g}(\lambda_1) & & & \\ & \hat{g}(\lambda_2) & & \\ & & \ddots & \\ & & & \hat{g}(\lambda_n) \end{bmatrix} =$$

$$\begin{bmatrix} \sum_{k=0}^{K-1} \theta_k T_k(\hat{\lambda_1}) & & & \\ & \sum_{k=0}^{K-1} \theta_k T_k(\hat{\lambda_2}) & & \\ & & \ddots & \\ & & & \sum_{k=0}^{K-1} \theta_k T_k(\hat{\lambda_n}) \end{bmatrix}$$

where θ_k is a vector of Chebyshev coefficients, which is trainable parameter.

Furthermore, Equation 32 can be deduced as following

$$
\begin{aligned}
f(\cdot_G)g_\theta = g_\theta(U\Lambda U^T)f = U\sum_{k=0}^{K-1}\theta_k T_k(\widetilde{\Lambda})U^T f = \sum_{k=0}^{K-1} U\theta_k T_k(\widetilde{\Lambda})U^T f \\
= \sum_{k=0}^{K-1} U\theta_k(\sum_{c=0}^{k}\alpha_{kc}\widetilde{\Lambda}^k)U^T f = \sum_{k=0}^{K-1}\theta_k(\sum_{c=0}^{k}\alpha_{kc}U\widetilde{\Lambda}^k U^T)f \qquad (33) \\
= \sum_{k=0}^{K}\theta_k(\sum_{c=0}^{k}\alpha_{kc}(U\widetilde{\Lambda}U^T)^k)f = \sum_{k=0}^{K-1}\theta_k T_k(U\widetilde{\Lambda}U^T)f = \sum_{k=0}^{K-1}\theta_k T_k(\widetilde{\mathcal{L}})f
\end{aligned}
$$

After using Chebyshev polynomial instead of the convolution kernel of the spectral domain, ChebNet does not need the Laplace matrix is to be eigen-decomposed. The most time-consuming steps are omitted [11].

Comparison between Spectral CNN and ChebNet
Assuming that n is the number of nodes.

- The parameter complexity of the SCNN model is very large, and the learning complexity is $O(n)$ [4], [11, Section 2.1], which is easy to overfit when there are many nodes. When dealing with large-scale graph data which usually has more than millions of nodes, it will face great challenges.
- Computing the eigenvalue decomposition of the Laplace matrix is very time-consuming.
- The convolution kernel of ChebNet has only K learnable parameters(θ_k), and $K \ll n$, hence their learning complexity is $O(K)$, the complexity of learnable parameters is greatly reduced [11, Section 2.1].
- ChebNet does not need the Laplace matrix to be eigen-decomposed, instead it approximate $g_\theta(\mathcal{L})$ with a truncated expansion in term of Chebyshev polynomials $T_k(x)$ of K^{th} order [11, Section 2.1].

6.3 CayleyNets

The paper [30] construct a family of complex filters that enjoy the advantages of Chebyshev filters while avoiding some of their drawbacks. A Cayley polynomial of order r to be a real-valued function with complex coefficients.

$$
g_{c,h}(\lambda) = c_0 + 2Re\{\sum_{j=1}^{r} c_j(h\lambda - i)^j(h\lambda + i)^{-j}\} \qquad (34)
$$

$c = (c_{0,\ldots,c_r})$ is a vector of one real coefficient and r complex coefficients and $h > 0$ is the spectral zoom parameter. A Cayley filter G is a spectral filter defined on real signals f by

$$
g_\theta(\mathcal{L})f = g_{c,h}(\Lambda)f = c_0 f + 2Re\{\sum_{j=1}^{r} c_j(h\mathcal{L} - iI)^j(h\mathcal{L} + iI)^{-j} f\} \qquad (35)
$$

the parameters c and h is learnable, which are optimized during training.

The application of the filter $g_\theta(\mathcal{L})f$ can be performed without explicit expensive eigendecomposition of the Laplacian operator. The unit complex circle is denoted by $e^{i\mathbb{R}} = \{e^{i\theta}, \theta \in \mathbb{R}\}$.

The Cayley transform $C(x) = \frac{x-i}{x+i}$ is a smooth bijection between $\mathbb{R}$ and $e^{i\mathbb{R}} \setminus \{1\}$.

Correspondingly, by applying the Cayley transform to the scaled Laplacian $h\mathcal{L}$, we get the complex matrix

$$C(h\mathcal{L}) = (h\mathcal{L} - iI)(h\mathcal{L} - iI)^{-1} \tag{36}$$

which has its spectrum in $e^{i\mathbb{R}}$ and is thus unitary.

Since $z^{-1} = \overline{z}$ for $z \in e^{i\mathbb{R}}$, we have $\overline{c_j C^j(h\mathcal{L})} = \overline{c_j} C^{-j}(h\mathcal{L})$ and given $2Rez = z + \overline{z}$, any Cayley filter can be written as a conjugate-even Laurent polynomial.

$$g_\theta = c_0 I + 2Re\{\sum_{j=1}^{r} c_j (h\mathcal{L} - i)^j (h\mathcal{L} + i)^{-j} f\} \tag{37}$$

proof:

$$g_\theta(\mathcal{L}) = c_0 I + \sum_{j=1}^{r} [c_j C^j(h\Delta) + \overline{c_j} C^{-j}(h\Delta)] =$$
$$c_0 I + \sum_{j=1}^{r} [c_j C^j(h\Delta) + \overline{c_j C^j(h\Delta)}] = c_0 I + 2Re\{\sum_{j=1}^{r} c_j (h\mathcal{L} - iI)^j (h\mathcal{L} + iI)^{-j} f\}$$

Since the spectrum of $C(h\Delta)$ is in $e^{i\mathbb{R}}$, the operator $C^j(h\Delta)$ can be thought of as a multiplication by a pure harmonic in the frequency domain $e^{i\mathbb{R}}$ for any integer power j,

$$C^j(h\mathcal{L}) = Udiag([C(h\lambda_1)]^j, ..., [C(h\lambda_n)]^j)U^T \tag{38}$$

it is a (real-valued) trigonometric polynomial, and $g_\theta(\Lambda)$ is conjugate-even.

Hence, a Cayley filter g_θ can be seen as a multiplication by a finite Fourier expansion in the frequency domain $e^{i\mathbb{R}}$. While preserving spatial locality, ChebNet can be considered as a special case of CayleyNet [30], [43].

6.4 GCN

GCN [23] can be regarded as a further simplification of ChebNet. To reduce the computational complexity, only the first order Chebyshev polynomials are considered, consequently each convolution kernel has only one trainable parameter [23]. Combining with (30), we have

$$g_\theta(\Lambda) = \sum_{k=0}^{1} \theta_k T_k(\widetilde{\Lambda}) \tag{39}$$

Hence,

$$g_\theta(\Lambda) = \begin{bmatrix} \sum_{k=0}^{1} \theta_k T_k(\hat{\lambda_1}) & & & \\ & \sum_{k=0}^{1} \theta_k T_k(\hat{\lambda_2}) & & \\ & & \ddots & \\ & & & \sum_{k=0}^{1} \theta_k T_k(\hat{\lambda_n}) \end{bmatrix} \tag{40}$$

In this linear formulation of a GCN we further approximate $\lambda_{max} \approx 2$. Under such approximations, this can simplifies to:

$$\widetilde{\mathcal{L}} = \frac{2}{\lambda_{max}}\mathcal{L} - I_n = \mathcal{L} - I_n \tag{41}$$

where $\mathcal{L}$ is normalized graph Laplacian $\mathcal{L} = I - D^{-\frac{1}{2}}AD^{-\frac{1}{2}}$.

Then,

$$f(\cdot_G)g = \sum_{k=0}^{1} \theta_k T_k(\widetilde{\mathcal{L}})f = \theta_0 T_0(\widetilde{\mathcal{L}})f + \theta_1 T_1(\widetilde{\mathcal{L}})f \tag{42}$$

where A is an adjacency matrix of the graph.

Accordingly,

$$f(\cdot_G)g = (\theta_0 + \theta_1(\mathcal{L} - I_n))f = (\theta_0 - \theta_1(D^{-\frac{1}{2}}AD^{\frac{1}{2}}))f \tag{43}$$

Furthermore, to reduce the number of trainable parameters——each kernel has only one trainable parameter, we set $\theta_0 = -\theta_1 = \theta$, then we have

$$f(\cdot_G)g \approx (\theta_0 + \theta_1(\mathcal{L} - I_n))f = \theta_0 - \theta_1 D^{-\frac{1}{2}}AD^{-\frac{1}{2}} = (\theta(D^{-\frac{1}{2}}AD^{-\frac{1}{2}} + I_n))f \tag{44}$$

where $D^{-\frac{1}{2}}AD^{-\frac{1}{2}} + I_n$ now has eigenvalues in the range [0, 2]. Then, only one parameter in convolution kernel can be learned. The number of parameters is greatly reduced, which can reduce the number of parameters to prevent overfitting.

However, repeated application of this operator can therefore lead to numerical instabilities and exploding or vanishing gradients. To alleviate this problem, the following re-normalization trick is introduced.

We add self-loop to A,

$$\widetilde{A} = A + I_n \tag{45}$$

Correspondingly,

$$\widetilde{D}_{i,i} = \sum_{j=1}^{n} \widetilde{A}_{i,j} \tag{46}$$

Finally,

$$f(\cdot_G)g = \theta\widetilde{D}^{-\frac{1}{2}}\widetilde{A}\widetilde{D}^{-\frac{1}{2}}f \tag{47}$$

Usually, we write θ as W, $\hat{A} = \widetilde{D}^{-\frac{1}{2}}\widetilde{A}\widetilde{D}^{-\frac{1}{2}}$, then we have $f(\cdot_G)g = \hat{A}fW$.

Here make an illustration of example(applied on Cora dataset, a node level task), consider a two-layer GCN for semi-supervised node classification on a graph, $f \in \mathbb{R}^{n \times C}$ is n nodes with C input channels

$$Z = softmax(\hat{A}ReLU(\hat{A}fW^{<0>})W^{<1>}) \tag{48}$$

$W^{<0>} \in \mathbb{R}^{C \times H}$ is an input-to-hidden weight matrix for a hidden layer with H feature maps. $W^{<1>} \in \mathbb{R}^{H \times F}$ is a hidden-to-output weight matrix, F is the dimension of feature maps in the output layer.

For calculation of loss function, need to evaluate the cross-entropy error over all labeled examples

$$Loss = -\sum_{l \in \gamma_L} \sum_{f=1}^{F} Y_{l,f} ln Z_{l,f} \tag{49}$$

where γ_L is the set of node indices that have labels, labels are denoted by Y_i. we then can use Stochastic Gradient descent as optimizer to finish the process of training.

7 Accelerated filtering using Lanczos method

Given graph $\mathcal{G}$ and its corresponding Laplacian matrix $\mathcal{L}$, a non-zero vector $f \in \mathbb{R}^n$, we apply Lanczos algorithm [15, Section 10.2] as shown in Algorithm 11 to compute an orthonormal basis $V_M = [v_1, ...v_M]$ of the Krylov subspace $K_M(\mathcal{L}, f) = span\{f, \mathcal{L}f, ..., \mathcal{L}^{M-1}f\}$.

Lanczos algorithm can form a symmetric tridiagonal matrix $H_M \in \mathbb{R}^{M \times M}$

$$V_M^* \mathcal{L} V_M = H_M = \begin{bmatrix} \alpha_1 & \beta_2 & & & \\ \beta_2 & \alpha_2 & \beta_3 & & \\ & \beta_3 & \alpha_3 & \ddots & \\ & & \ddots & \ddots & \beta_M \\ & & & \beta_M & \alpha_M \end{bmatrix} \tag{50}$$

Algorithm 1: Lanczos method

Input: Symmetric matrix $\mathcal{L} \in \mathbb{R}^{n\times n}$, vector $f \neq 0$, $M \in \mathbb{N}$
Result: $V_M = [v_1, ..., v_M]$ with orthonormal columns, scalars $\alpha_1, ..., \alpha_M, \beta_2, ..., \beta_M \in \mathbb{R}$.

$v_1 \leftarrow f/\|f\|_2$;
for $j := 1$ **to** M **do**
  $w = \mathcal{L}v_j$;
  $\alpha_j = v_j^* w$;
  $\tilde{v}_{j+1} = w$ - $v_j\alpha_j$;
  if $j > 1$ **then**
    $\tilde{v}_{j+1} \leftarrow \tilde{v}_{j+1}$ - $v_{j-1}\beta_{j-1}$;
  end
  $\beta_j = \|\tilde{v}_{j+1}\|_2$;
  $\tilde{v}_{j+1} = \tilde{v}_{j+1}/\beta_j$
end

The approximation to $g_\theta(\mathcal{L})f$ is given by [13], [40]

$$g_\theta(\mathcal{L})f \approx \|f\|_2 V_M g_\theta(H_M)e_1 := g_M \tag{51}$$

where $e^1 \in \mathbb{R}^M$ is the first unit vector. Because eigenvalue interlacing [4] [19], the eigenvalues of H_M are contained in the interval $[0, \lambda_{max}]$ and hence the expression $g_\theta(H_M)$ is well-defined [40]. Particularly, $M \ll n$, the computational cost by evaluating $g_\theta(H_M)$ is inexpensive.

Theorem 2 ([18, Corollary 3.4]). *Let $\mathcal{L} \in \mathbb{R}^{n\times n}$ be symmetric with eigenvalues contained in the interval [0, λ_{max}] and let $g_\theta : [0, \lambda_{max}] \to \mathcal{R}$ be continuous. Then*

$$||g_\theta(\mathcal{L}f - g_M)\|_2 \leq 2\|f\|_2 \cdot \min_{p\in\mathcal{P}_{M-1}} \max_{z\in[0,\lambda_{max}]} |g_\theta(z) - p(z)| \tag{52}$$

where $\mathcal{P}_{M-1}$ denotes all polynomials of degree at most $M-1$.

According to Theorem 2 the error is bounded by the best polynomial approximation [32, Theorem 2.4.1] of g_θ on $[0, \lambda_{max}]$. The paper [40] demonstrates that – up to a multiple of two – the Lanczos-based approximation g_θ can be expected to provide at least the same accuracy. In addition, the Lanczos-based approximation can sometimes be expected to perform much better because of its ability to adapt to the eigenvalues of $\mathcal{L}$ [40], which can be well-understand for Krylov subspace approximations to solutions of linear systems [17, Section 3.1].

[4] Consider two sequences if real numbers: $\lambda_1 \geq \lambda_2 \ldots \geq \lambda_n$, and $\mu_1 \geq \mu_2 \ldots \geq \mu_n$ with $m < n$. The second sequence is said to interlace the first one whenever $\lambda_i \geq \mu_i \geq \lambda_{n-m+i}$ for $i = 1, \ldots, m$.

8 Acknowledgement

I would like to appreciate my supervisor Dr. Stefan Güttel patiently correcting these notes, which are part of my first-year Ph.D. research report.
